4 Abstract

Long-term monitoring datasets can provide information to interpret the effects of environmental changes or management actions on ecosystem condition. The ability to link causal effects with potential changes from observed data can partly depend on the chosen method of trend analysis. Two statistical approaches, weighted regression on time, discharge, and season (WRTDS) and generalized additive models (GAMs), have recently been used to evaluate long-term trends in chlorophyll time series in estuarine systems. Both models provide a similar approach to trend analysis by using context-dependent parameters or smoothing functions that vary continuously 11 and have the potential to identify multiple drivers of change. However, the quantitative capabilities of each model, including descriptions of observed and flow-normalized trends, have not been rigorously compared to determine most appropriate use of each model. We evaluated WRTDS and GAMs using thirty years of data for a monthly time series of chlorophyll in the Patuxent River Estuary, a well-studied tributary to Chesapeake Bay. Each model was evaluated based on predictive capabilities of the observed data and ability to reproduce flow-normalized trends with simulated data that had statistical properties comparable to the original dataset. Each model was also evaluated based on concordance of conclusions of water quality changes, and causes thereof, in different time periods. For all examples, WRTDS had lower prediction error than GAMs, although differences were minor compared to computational requirements of each 21 model. Comparisons of flow-normalized trends revealed distinct differences in temporal variation in chlorophyll a (chl-a) from the upper to lower Patuxent estuary. Mainstem influences of the Chesapeake Bay were apparent with a slight increase in chl-a trends over time in the lower 24 estuary, whereas flow-normalized predictions for the upper estuary showed declines in chl-a followed by an increase in recent years. Both models had comparable abilities to remove flow effects in simulated time series of chl-a, although flow-normalized predictions to actual data suggested GAMs results were more stable with minimal observations. This information will provide researchers with valuable guidance for using statistical models in trend evaluation, with particular relevance for computational requirements, desired products, and future data needs. Key words: chlorophyll, estuary, generalized additive models, Patuxent River Estuary, trend analysis, weighted regression

1 Introduction

The interpretation of environmental trends can have widespread implications for the 34 management of natural resources and can facilitate an understanding of ecological factors that mediate system dynamics. An accurate interpretation of trends can depend on the chosen method of analysis, and more importantly, its ability to consider effects of multiple drivers on response endpoints that may be particular to the system of interest. The need to interpret potential impacts 38 of nutrient pollution has been a priority issue for managing aquatic resources (Nixon 1995), 39 particularly for estuaries that serve as focal points of human activities and receiving bodies for upstream hydrologic networks (Paerl et al. 2014). Common assessment endpoints for eutrophication in estuaries have included seagrass growth patterns (Steward and Green 2007), frequency and magnitude of oxygen depletion in bottom waters (Paerl 2006), and trophic network 43 connectivity (Powers et al. 2005). Additionally, chlorophyll concentration provides a measure of the release of phytoplankon communities from nutrient limitation with increasing eutrophication. Chlorophyll time series have been collected for decades in tidal systems (e.g., Tampa Bay, TBEP (Tampa Bay Estuary Program) (2011); Chesapeake Bay, Harding (1994); datasets cited in Monbet (1992), Cloern and Jassby (2010)), although the interpration of trends in observed data has been problematic given the inherent variability of time series data. Identifying the response of chlorophyll to different drivers, such as management actions or increased pollutant loads, can be confounded by natural variation from freshwater inflows (Borsuk et al. 2004) or tidal exchange with oceanic outflows (Monbet 1992). Seasonal and spatial variability of chlorophyll dynamics (see Cloern (1996)) can further complicate trend evaluation, such that relatively simple analysis 53 methods may insufficiently describe variation in long-term datasets (Hirsch 2014). More rigorous quantitative tools are needed to create an unambiguous characterization of chlorophyll response independent of variation from confounding variables.

Recent applications of statistical methods to describe water quality dynamics have shown promise in estuaries, specifically weighted regression on time, discharge, and season (WRTDS) and generalized additive modelss (GAMs). The WRTDS method was initially developed to describe water quality trends in rivers (Hirsch et al. 2010, Hirsch and De Cicco 2014) and has recently been adapted to describe chlorophyll trends in tidal waters (Beck and Hagy III 2015). A

{acro:WRTI

defining characteristic of WRTDS is a weighting scheme that fits a continuous set of parameters to the time series by considering the influence of location in the record and contextual flow inputs to the period of interest. The WRTDS model has been used to model pollutant delivery from tributary sources to Chesapeake Bay (Hirsch et al. 2010, Moyer et al. 2012, Zhang et al. 2013), Lake Champlain (Medalie et al. 2012), and the Mississippi River (Sprague et al. 2011). A comparison to an alternative regression-based model for evaluating nutrient flux, ESTIMATOR, suggested that WRTDS can produce more accurate trend estimates (Moyer et al. 2012). Similarly, GAMs can be used to describe variation in a response variable as a sum of smoothing functions for different predictors (Hastie and Tibshirani 1990, Wood 2006). In applications to water quality time series, GAMs are similar to WRTDS in that variable effects through time can be described in relation to seasonal or annual changes. Application of GAMs to describe eutrophication endpoints in tidal waters have not been as extensive as WRTDS, although exploratory analyses have suggested that results are comparable. Moreoever, GAMs are particularly appealing because they are less computationally intense and provide more accessible estimates of model uncertainty than WRTDS. Despite the potential for both approaches to characterize system dynamics, the relative merits of each have not been evaluated. Quantitative comparisons that describe the accuracy of empirical descriptions and the desired products could inform the use of each model to 78 describe long-term changes in ecosystem characteristics.

The goal of this study is to provide an empirical description of the relative abilities of 80 WRTDS and GAMs to describe long-term changes in time series of eutrophication response endpoints in tidal waters. A thirty year time series of monthly chlorophyll observations from the 82 Patuxent River Estuary is used as a common dataset for evaluating each model. The Patuxent 83 Estuary is a well-studied tributary of the Chesapeake Bay system that has been monitored for several decades with fixed stations along the longitudinal axis. Two stations were chosen as representative time series that differed in the relative contributions of watershed inputs and influences from the mainstem of the Chesapeake, in addition to known historical events that have impacted water quality in the estuary. The specific objectives of the analysis were to 1) provide a 88 narrative comparison of the statistical foundation of each model, both as a general description and as a means to evaluate water quality time series, 2) use each model to develop an empirical description of water quality changes at each monitoring station given known historical changes in

water quality drivers, 3) evaluate each models's ability to reproduce flow-normalized trends as
known components of simulated time series, and 4) compare each technique's ability to describe
changes, as well as the differences in the information provided by each. We conclude with
recommendations on the most appropriate use of each method, with particular attention given to
computational requirements, uncertainty assessment, and potential needs for additional
monitoring data.

98 2 Methods

2.1 Study site and water quality data

The Patuxent River estuary, Maryland, is a tributary to Chesapeake Bay on the Atlantic 100 coast of the United States (Fig. 1). The longitudinal axis extends 65 km landward from the 101 confluence with the mesohaline portion of Chesapeake Bay. Estimated total volume at mean low 102 water is 577 x 10⁶ m³ and a surface area of 126 x 10⁶ m². The lower estuary (below 45 km from the confluence) has a mean width of 2.2 km and depth of 6 m (Cronin and Pritchard 1975), 104 whereas the upper estuary has a a mean width of 0.4 km and mean depth of 2.5 m (Hagy 1996). 105 The lower estuary is seasonally stratified and vertically-mixed in the upper estuary. A two-layer 106 circulation pattern occurs in the lower estuary characterized by an upper seaward-flowing layer 107 and a lower landward-flowing layer. A mixed diurnal tide dominates with mean range varying from 0.8 m in the upper estuary to 0.4 m near the mouth (Boicourt and Sanford 1998). The 109 estuary drains a 2300 km² watershed that is 49% forest, 28% grassland, 12% developed, and 10% 110 cropland (Jordan et al. 2003). The US Geological Survey (USGS) stream gage on the Patuxent 111 River at Bowie, Maryland measures discharge from 39% of the watershed. Daily mean discharge 112 from 1985 to 2014 was 11.0 m³ s⁻¹, with abnormally high years occuring in 1996 (annual mean $20.0 \text{ m}^3 \text{ s}^{-1}$) and 2003 (annual mean 22.5 m³ s⁻¹). 114

The Chesapeake Bay Program maintains a continuous monitoring network for the
Patuxent at multiple fixed stations that cover the salinity gradient from estuarine to tidal fresh
(http://www.chesapeakebay.net/, Fig. 1 and Table 1). Water quality samples have been collected
since 1985 at monthly or bimonthly intervals and include salinity, temperature, chlorophyll *a* (chl-*a*), dissolved oxygen, and additional dissolved or particulate nutrients and organic carbon.
Seasonal variation in chl-*a* is observed across the stations with spring and summer blooms

{acro:USG

{acro:chla

occuring in the upper, oligohaline section, whereas primary production is generally higher in the lower estuary during winter months (Fig. 2). Chlorophyll concentrations are generally lowest for 122 all stations in late fall and early winter. Periods of low flow are associated with higher chlorophyll 123 concentrations in the upper estuary, whereas the opposite is observed for high flow. Stations 124 TF1.6 and LE1.2 were chosen as representative time series from different salinity regions to 125 evaluate the water quality models. Observations at each station capture a longitudinal gradient of 126 watershed influences at TF1.6 to mainstem influences from the Chesapeake Bay at LE1.2. 127 Long-term changes in chlorophyll have also been related to historical reductions in nutrient inputs 128 following a statewide ban on phosphorus-based detergents in 1984 and wastewater treatment 129 improvements in the early 1990s that reduced point sources of nitrogen (Lung and Bai 2003, Testa et al. 2008). Therefore, the chosen stations provide unique datasets to evaluate the 131 predictive and flow-normalization abilities of each model given the differing contributions of 132 landward and seaward influences on water quality. 133

Thirty years of monthly chlorophyll and salinity data from 1986 to 2014 were obtained for 134 stations TF1.6 and LE1.2 from the Chesapeake Bay Program data hub (http://www.chesapeakebay.net/data). All data were vertically integrated throughout the water 136 column for each date to create a representative sample of water quality. The integration averaged 137 all values after interpolating from the surface to the maximum depth. Observations at the most 138 shallow and deepest sampling depth were repeated for zero depth and maximum depths, 139 respectively, to bound the interpolations within the range of the data. Daily flow data were also obtained from the USGS stream gage station at Bowie, Maryland and merged with the nearest 141 date in the chorophyll and salinity time series. Initial analyses suggested that a moving-window 142 average of discharge for the preceding five days provided a better fit to the chlorophyll data at 143 TF1.6, whereas the continuous salinity record was used as a tracer of discharge at LE1.2. Both chlorophyll and discharge data were log-transformed. Censored data were not present in any of the data sets. Initial quality assurance checks for all monitoring data were conducted following standard protocols adopted by the Chesapeake Bay Program.

2.2 Model descriptions

149

2.2.1 Weighted Regression on Time, Discharge, and Season

The WRTDS method relates a response endpoint, typically a nutrient concentration, to discharge and time to evaluate long-term trends (Hirsch et al. 2010, Hirsch and De Cicco 2014).

Recent adaptation of WRTDS to tidal waters relates chlorophyll concentration to salinity and time (Beck and Hagy III 2015), where salinity is a tracer of freshwater inputs or tidal changes. The functional form of the model is a simple regression that relates the natural log of chlorophyll (Chl) to decimal time (T) and salinity (Sal) on a sinuisoidal annual time scale (i.e., cyclical variation by year).

$$\ln\left(Chl\right) = \beta_0 + \beta_1 T + \beta_2 Sal + \beta_3 \sin\left(2\pi T\right) + \beta_4 \cos\left(2\pi t\right) + \epsilon \tag{1} \quad \{\text{eqn:funfe}\}$$

The tidal adaptation of WRTDS uses quantile regression models (Cade and Noon 2003) to 157 characterize trends in different conditional distributions of chlorophyll, e.g., the median or 90th percentile. For comparison to GAMs, the original WRTDS model in Hirsch et al. (2010) that 159 characterizes the conditional mean of the response was used. Mean models require an estimation 160 of the back-transformation bias parameter for response variables in log-space. This is achieved 161 using the standard error of residuals for each observation along the time series during 162 back-transformation (Hirsch et al. 2010). Additionally, the WRTDS model uses survival regression as a variation of the weighted Tobit model (Tobin 1958) to account for censored 164 observations beyond the detection limit (Hirsch and De Cicco 2014). 165

The WRTDS approach obtains fitted values of the response variable by estimating regression parameters for each unique observation. Specifically, a unique regression model is estimated for each point in the period of observation. Each model is weighted by month, year, and salinity (or flow) such that a unique set of regression parameters for each observation is obtained. For example, a weighted regression centered on a single observation weights other observations in the same year, month, and similar salinity with higher importance, whereas observations different months, years, or salinities receive lower importance. This weighting approach allows estimation of regression parameters that vary in relation to observed conditions throughout the period of record (Hirsch et al. 2010). Optimal window widths can be identified using

cross-validation, described below, that evaluates the ability of the model to generalize results with novel datasets.

Predicted values are based on an interpolation matrix from the unique regressions at each time step. A sequence of salinity or flow values based on the minimum and maximum values for the data are used to predict chlorophyll using the observed month and year based on the parameters fit to the observation. Model predictions are based on a bilinear interpolation from the grid using the salinity (flow) and date values closest to observed. Salinity- or flow-normalized values are also obtained from the prediction grid that allow an interpretation of chlorophyll trend that is independent of variation related to freshwater inputs. Normalized predictions are obtained for each observation by collecting the sample of observed salinity or flow values that occur for the same month throughout all years in the dataset. These values are assumed to be equally likely to occur across the time series at that particular month. A normalized value for each point in the time series is the average of the predicted values from each specific model based on the salinity or flow values that are expected to occur for each month.

2.2.2 Generalized Additive Models

A GAM is a statistical model that allows for a linear predictor to be represented as the 190 sum of multiple smooth functions of covariates (Hastie and Tibshirani 1990). In this application, GAMs were constructed with the same explanatory variables as the WRTDS approach: log of 192 chl-a was modeled as a function of decimal time, salinity or flow, and day of year (i.e., to capture 193 the annual cycle). The relationships between log-chl-a and the covariates were modeled with thin plate regression splines (Wood 2006) as the smooth functions using the 'mgcv' package in R. To 195 allow for interaction between the model covariates (e.g., seasonal differences in the long-term 196 chl-a pattern), a tensor product basis between all three covariates was constructed. The tensor 197 product basis allows for the smooth construct to be a function of any number of covariates, 198 without an isotropy constraint. The GAM implementation in 'mgcv' does not require the selection of knots for a spline basis, but instead a reasonable upper limit on the flexibility of the 200 function is set, and a 'wiggliness' penalty is added to create a penalized regression spline structure. The balance between model fit and smoothness is achieved by selecting a smoothness 202 parameter that minimizes the generalized cross-validation score (Wood 2006). 203

Model predictions with GAMs are straightforward to obtain after the model parameters

are selected, and can be obtained along with standard errors which are based on the Bayesian posterior covariance matrix (Wood 2006). For this comparison, salinity- or flow-normalized GAM predictions were obtained in a manner for consistency with WRTDS. The observed salinity or flow values were compiled that occurred in the same month throughout all years in the dataset. These values were assumed to be equally likely to occur at that particular month. A normalized GAM estimate at each date in the record was computed as the average of the predictions obtained using all of the flow or salinity values for that month of the year throughout the record.

2.2.3 Selection of model parameters

The selection of optimal model parameters is a challenge that represents a tradeoff between model precision and ability to generalize to novel datasets. Weighted regression requires identifying optimal half-window widths, whereas the GAM approach used here requires identifying an optimal value for a smoothing parameter that weights the wiggliness of the function against model fit (Wood 2006). Overfitting a model with excessively small window widths or smoothing parameter will minimize prediction error but prevent extrapolation of results to different datasets. Similarly, underfitting a model with large window widths or smoothing parameter will reduce precision but will improve the ability to generalize results to different datasets. From a statistical perspective, the optimal model parameters provide a balance between over- and under-fitting. Both models use a form of cross-validation to identify model parameters that maximize the precision of model predictions with a novel dataset.

The basic premise of cross-validation is to identify the optimal set of model parameters that minimize prediction error on a dataset that was not used to develop the model. For the GAM approach, generalized cross-validation is used to obtain the optimal smoothing parameter in an iterative process with penalized likelihood maximization to solve for model coefficients. The effective degrees of freedom of the resulting model varies with the smoothing parameter (Wood 2006). Similarly, the tidal adaptation of WRTDS used k-fold cross-validation to identify the optimal half-window widths. For a given set of half-window widhts, the dataset was separated into ten disjoint sets, such that ten models were evaluated for every combination of k - 1 training and remaining test datasets. That is, the training dataset for each fold was all k - 1 folds and the test dataset was the remaining fold, repeated k times. The average prediction error of the test datasets across k folds provided an indication of model performance for the given combination of

half-window widths. The optimum window widths were those that provided minimum errors on
the test data. Evaluating multiple combinations of window-widths can be computationally
intensive. An optimization function was implemented in R (Byrd et al. 1995, RDCT (R

Development Core Team) 2015) to more efficiently evaluate model parameters using a search
algorithm. Window widths were searched using the limited-memory modification of the BFGS
quasi-Newton method that imposes upper and lower bounds for each parameter. The chosen
parameters were based on a selected convergence tolerance for the error minimization of the
search algorithm.

2.3 Comparison of modelled trends

Separate WRTDS and GAMs were created using the above methods for the chlorophyll time series at TF1.6 and LE1.2. Initial analyses indicated that model performance could be improved using the flow record to model chl-*a* at TF1.6 and the salinity record to model chl-*a* at LE1.2. For each model and station, a predicted and flow-normalized (hereafter flow-normalized refers to both flow and salinity) time series was obtained for comparison. The results were compared using several summary statistics that evaluated both the predictive performance to describe observed chlorophyll and direct comparisons between the models. Emphasis was on agreement between observed and predicted values, rather than uncertainty associated with parameter estimates or model results. As of writing, methods for estimating confidence intervals of WRTDS have been developed for the original model (Hirsch et al. 2015), but have not been fully developed for application to WRTDS in tidal waters. In addition to simple visual evaluation of trends over time, summary statistics used to compare model predictions to observed chl-*a* included root mean square error (RMSE) and average differences. For all comparisons, RMSE comparing each model's predictions to observed chl-*a* (fit) was defined as:

{acro:RMS

$$RMSE_{fit} = \sqrt{\frac{\sum_{i=1}^{n} \left(Chl_i - \widehat{Chl}_i\right)^2}{n}}$$
 (2)

where n is the number of observations for a given evaluation, Chl_i is the observed value of chl-a for observation i, and $\widehat{Chl_i}$ is the predicted value of chl-a for observation i. RMSE values closer to zero represent model predictions closer to observed. Comparisons between models using

RMSE are similar, such that:

$$RMSE_{btw} = \sqrt{\frac{\sum_{i=1}^{n} \left(\widehat{Chl}_{WRTDS,i} - \widehat{Chl}_{GAM,i}\right)^{2}}{n}}$$
(3) {rmse_fun}

where the estimated chl-a values for each model, $\widehat{Chl}_{i,WRTDS}$ and $\widehat{Chl}_{i,GAM}$, are compared directly. Similarly, average differences (or bias) of predictions between models as a percentage was defined as:

Positive values indicate that WRTDS provided higher predictions than GAMs on average,

Average difference =
$$\left(\frac{\sum_{i=1}^{n} \widehat{Chl}_{WRTDS,i} - \sum_{i=1}^{n} \widehat{Chl}_{GAM,i}}{\sum_{i=1}^{n} \widehat{Chl}_{GAM,i}} \right) * 100$$
 (4) {avediff_

whereas the opposite is true for negative values (Moyer et al. 2012). Results between models 266 were also evaluated using regressions comparing the WRTDS and GAM predictions. The regressions were compared to a null model having an intercept of zero and slope of one. 268 Deviation of either the intercept or slope of the regressions from the null model provided evidence 269 of systematic differences between the models. In general, an intercept significantly different from zero can be interpreted as an overall difference between the predictions, whereas a slope different 271 from one can be interpreted as a difference that varies with relative magnitude of the predictions. The statistical comparisons described above were conducted for the entire time series at 273 each station to evaluate overall performance. Different time periods were also evaluated to 274 identify potential temporal variation in results, which included a comparison of results by annual 275 and seasonal aggregations and periods with different levels of flow using the discharge record at Bowie, Maryland. Annual and seasonal aggregations shown in Fig. 2 were evaluated between the models, in addition to evaluating the models at different levels of flow defined by the quartile 278 distributions (min-25%, 25%-median, median-75%, and 75%-max). Flow-normalized time 279 series were compared similarly but only between the models because the true flow-independent 280 component of the observed data is not known and can only be empirically estimated. As 281 described below, an evaluation of flow-normalized data for each model was accomplished using simulated datasets with known components that were independent of discharge. However, a 283

simple comparison of flow-normalized trends by different time periods summarized long-term patterns in the Patuxent River estuary. These comparisons evaluated percent changes of 285 flow-normalized estimates at the beginning and end of each time period. Percent changes within 286 each period were based on annual mean estimates for the first and last three years of 287 flow-normalized chl-a estimates, excluding the annual aggregations that had limited annual mean 288 data (i.e., seven years per period). For example, percent change for the 289 January-February-March (JFM) seasonal period compared an average of JFM annual means for 290 1986 through 1988 to an average of JFM annual means for 2012 through 2014. This approach 291 was used to reduce the influence of abnormal years or missing data on trend estimates. 292

2.4 Comparison of flow-normalized trends

300

301

308

309

310

311

The relative abilities of each model to characterize flow-normalized trends in chlorophyll were evaluated using simulated datasets with known components. This approach was used because the flow-independent component of chlorophyll is typically not observed in raw data such that the true signal must be empirically estimated. Accordingly, the ability of each model to isolate the flow-normalized trend cannot be evaluated with reasonable certainty unless the true signal is known. Simulated time series of observed chlrophyll (Chl_{obs}) were created as additive components related to flow (Chl_{flo}) and a flow-independent biological component of chlorophyll (Chl_{bio}) :

$$Chl_{obs} = Chl_{flo} + Chl_{bio}$$
 (5) {chlobs}

{acro:JFM

A distinction between Chl_{flo} and Chl_{bio} is that the former describes variation in the observed time series with changes in discharge (e.g., concentration dilution with increased flow) and the latter describes a true, desired measure of chlorophyll in the water column that is directly linked to primary production. The biological component of chlorophyll is comparable to an observation in a closed system that is not affected by flow and is the time series that is estimated by flow-normalization with WRTDS and GAMs.

The simulated time series was created using methods similar to those in Hirsch et al. (2015) and was based on a stochastic model derived from actual flow and water quality measurements to ensure the statistical properties were comparable to existing datasets. This approach allowed us to evaluate GAMs and WRTDS under different sampling regimes (e.g.,

monthly rather than daily), while ensuring the simulated datasets had statistical properties that were consistent with known time series. Daily flow observations from the USGS stream gage 313 station 01594440 near Bowie, Maryland (38°57′21.3″N, 76°41′37.3″W) were obtained from 1985 314 to 2014. Daily chlorophyll records were obtained from the Jug Bay station (38°46′50.6″N, 315 76°42′29.1″W) of the Chesapeake Bay Maryland National Estuarine Research Reserve in the 316 upper Patuxent. Daily chlorophyll concentrations were estimated from fluorescence values that did not include blue-green algae blooms. Our primary concern was simulating chlorophyll 318 concentrations at monthly or bimonthly timesteps such that taxa-specific concentrations on a 319 daily time step were not relevant. 320

Four time series were estimated or simulated from the actual datasets to create the complete, simulated time series: 1) estimated discharge as a stationary seasonal component (\widehat{Q}_{seas}) , 2) simulated error structure from the residuals of the seasonal discharge model $(\varepsilon_{Q,sim})$, 3) estimated chlorophyll independent of discharge as a stationary seasonal component (\widehat{Chl}_{seas}) , and 4) simulated error structure from the residuals of the seasonal chlorophyll model $(\varepsilon_{Chl,sim})$. Unless otherwise noted, chlorophyll and discharge are in ln-transformed units. Each of the four components was used to simulate the components in eq. (5):

328

$$Chl_{flo} = I\left(\hat{Q}_{seas} + \sigma \cdot \varepsilon_{Q,sim}\right) \tag{6}$$

$$Chl_{bio} = \widehat{Chl}_{seas} + \sigma \cdot \varepsilon_{Chl,sim} \tag{7}$$

The estimated flow time series within the parentheses, $\hat{Q}_{seas} + \sigma \cdot \varepsilon_{Q,sim}$, is floored at zero to simulate an additive effect of increasing flow on Chl_{obs} . Although the actual relationship of water 330 quality measurements with flow is more complex, we assumed that a simple addition was 331 sufficient for the simulations where the primary objective was to create an empirical and linear 332 link between flow and chlorophyll. Moreover, the vector I (where $0 \le I \le 1$) can be manually 333 changed to represent an independent effect of flow based on the desired simulation. For example, 334 a flow effect that changes from non-existent to positive throughout the period of observation can 335 be simulated by creating a vector ranging from zero to one. For the simulated Chl_{bio} time series, 336 the seasonal and error components were characterized using the daily time series at Jug Bay that 337 likely included an effect of flow in the observed data. For the simulated models, we assumed that

the actual flow effect was part of the seasonal component to obtain an accurate estimate of the error component that was independent of both flow and season. Methods for estimating each of the components in eqs. (6) and (7) are described in detail below.

340

341

342

343

345

357

358

359

360

361

First, a model for simulating flow-related chlorophyll (eq. (6)) was estimated from the stream gage data as the additive combination of a stationary seasonal component and serially-correlated errors:

$$Q_{seas} = \beta_0 + \beta_1 \sin(2\pi T) + \beta_2 \cos(2\pi T)$$
 (8) {qseas}

 $\varepsilon_Q = Q_{seas} - \hat{Q}_{seas}$ (9) {qerr}

{acro:ARM

{acro:AIC

A seasonal model of flow was estimated using linear regression for time, T, on an annual sinusoidal period (eq. (8)). The residuals from this regression, ε_Q (eq. (9)), were used to estimate 347 the structure of the error distribution for simulating the stochastic component of flow. The error 348 distribution was characterized using an Autoregressive Moving Average (ARMA) model to 349 identify appropriate p and q coefficients (Hyndman and Khandakar 2008). The parameters were 350 chosen using stepwise estimation for nonseasonal univariate time series that minimized Akaike 351 Information Criterion (AIC). The resulting coefficients were used to generate random errors from 352 a standard normal distribution for the length of the original time series, $\varepsilon_{Q, sim}$. These stochastic 353 errors were multiplied by the standard deviation of the residuals in eq. (9) and added to the 354 seasonal component in eq. (8) to create a simulated, daily time series of the flow-component for 355 chlorophyll, Chl_{flo} (eq. (6)). 356

The chlorophyll time series was created using a similar approach. The first step estimated the stationary seasonal component of the chlorophyll time series by fitting a WRTDS model (Hirsch et al. 2010) that explicitly included discharge from the gaged station using one year of data from the whole time series:

$$Chl_{seas} = \beta_0 + \beta_1 T + \beta_2 Q + \beta_3 \sin(2\pi T) + \beta_4 \cos(2\pi T)$$

$$\tag{10} \quad \{\text{chlseas}\}$$

$$\varepsilon_{Chl} = Chl_{seas} - \widehat{Chl}_{seas}$$
 (11) {chlerr}

This approach was used to isolate an error structure for simulation that was independent of flow

and biology, where the seasonal component (as time T on a sinusoidal annual period) was assumed to be related to biological processes. The error distribution was then estimated from the 364 residuals (eq. (11)) as before using an ARMA estimate of the residual parameters, p and q. 365 Standard error estimates from the regression used at each point in the one-year time series were 366 also retained for each residual. Errors were simulated ($\varepsilon_{Chl, sim}$, eq. (7)) for the entire year using 367 the estimated auto-regressive structure and multiplied by the corresponding standard error 368 estimate from the regression. The entire year was repeated for every year in the observed time 369 series. All simulated errors were rescaled to the range of the original residuals that were used to 370 estimate the distribution. Finally, the simulated flow-component, Chl_{flo} , was added to the 371 simulated bilogical model, Chl_{bio} , to create the final chlorophyll-flow time series, Chl_{obs} , in 372 eq. (5).

A daily time series for the entire period of record was simulated using the above methods 374 and then used to compare the relative abilities of WRTDS and GAMs to characterize 375 flow-normalized trends. Three time series with monthly sampling frequencies and varying 376 contributions of the flow component (Chl_{flo} in eq. (5)) were created from the daily time series (Fig. 7). One day in each month for each year was randomly sampled and used as the monthly 378 time step for each time series. Varying effects of the flow component on observed chlorophyll 379 were creating by multiplying Chl_{flo} by different indicator vectors (I in eq. (6)). The contribution 380 of the flow component varied from non-existent, constant, and steadily increasing. Respectively, 381 the vector of coefficients applied to each flow component was a constant vector of zeroes, a 382 constant vector of ones, and a linear increase starting at zero and ending at one. This created three 383 monthly time series that were used to evaluate each model that were analogous to no influence, 384 constant, and changing influence of the flow component over time (Fig. 7). Results were 385 evaluated by first comparing the predicted (\widehat{Chl}_{obs}) and observed (Chl_{obs}) chloropyll values for 386 each simulation, following by comparing the flow-normalized results (\widehat{Chl}_{bio}) from each model to 387 the original biological chlorophyll (Chl_{bio}) component of each simulated time series (eqs. (5) 388 and (7)). The former comparison provided information on relative fit to validate the simulated 389 data, whereas the latter comparison to evaluate flow-normalization was the primary focus of the 390 analysis. 391

3 Results

393

3.1 Observed trends and relative fit

The optimal half-window widths and degrees of freedom for smoothing varied for 394 WRTDS and GAMs, respectively, at each station. For WRTDS, optimal half-window widths 395 identified by generalized cross-validation were 0.25 as a proportion of each year, 13.59 years, and 396 0.25 as a proportion of the total range of salinity for LE1.2, and 0.25 of each year, 6.28 years, and 397 0.50 of flow at TF1.6. For both stations, the optimization method selected relatively wide 398 windows for the year weights while minimizing the seasonal (annual proportion) and flow component. For GAMs, the optimal smoothing procedure resulted in a smoother model at LE1.2 400 than TF1.6 with effective degrees of freedom of 32.2 and 47.1, respectively. The tensor product 401 smooth costruct does not split apart the effective degrees of freedom among the three interacting 402 parameters. 403

The predicted chl-a from each model generally followed patterns in observed chl-a from 404 1986 to 2014 (Fig. 3). At LE1.2, each model showed seasonal minimum typically in November, 405 whereas maximum chl-a was observed in a spring bloom, typically March or April (Fig. 4). A 406 secondary, smaller seasonal peak was also observed in late summer from bottom-layer 407 regeneration and upward nutrient transport (Testa et al. 2008), Visual comparison of results 408 between models showed that the secondary seasonal maxima at each site were more pronounced 409 for WRTDS estimates. Seasonal variation at TF1.6 was noticeably different with an initial peak 410 typically observed in May and a larger dominant bloom occurring in September or October 411 (Fig. 4). Elevated chl-a concentrations were also more prolonged than those at LE1.2 with only a 412 slight decrease between the two seasonal blooms. A seasonal minimum was typically observed in December or January, followed by a rapid increase in the following months. Differences in 414 magnitude of the seasonal range were also less prononced at LE1.2 compared to TF1.6, with 415 differences throughout the year averaging 3.5 μ g L⁻¹ of chl-a at LE1.2 and 9.5 μ g L⁻¹ of chl-a at 416 TF1.6. Visual evaluation of seasonal trends suggested each model provided similar results, 417 although WRTDS predictions had slightly better fits at the extreme ends of the distribution of chl-a (Fig. 3a). Normalized predictions for both models were visually distinct from observed predictions such that seasonal minima and maxima and extreme predictions were not common 420

with the normalized values. Overall, both models had predictions that provided a more adequate visual description of the range of chl-*a* at TF1.6 as compared to LE1.2 where observed values lower or higher than the predicted values were more common.

422

423

Quantitative summaries of model fit by site indicated that performance between sites and 424 models was similar with RMSE ranging from a minimum of 0.51 at LE1.2 for WRTDS 425 predictions and a maximum of 0.54 at TF1.6 for GAM predictions (Table 2). Overall, both 426 models performed similarly, although WRTDS had slightly lower RMSE for the overall time 427 series and all time periods (annual, seasonal, and flow) regardless of site (Table 2). Fit by different 428 time periods generally showed agreement between methods during periods when performance 429 was relatively high or low. For LE1.2, both models had the worst fit during the 2001-2007 annual 430 period (RMSE 0.63 for GAMs, RMSE 0.60 for WRTDS), the April-May-June (AMJ) seasonal periods (0.69 for GAMs, 0.64 for WRTDS), and periods of high flow (0.64 for GAMs, 0.63 for 432 WRTDS). For TF1.6, models had the worst fit during the 1994-2000 annual period (0.58 for 433 GAMs, 0.58 for WRTDS) and the AMJ seasonal period (0.60 for GAMs, 0.58 for WRTDS). 434 Error rates between models were comparable for all flow periods at TF1.6, with the exception of 435 lower error rates during low flow (0.48 for GAMs, 0.46 for WRTDS). In general, model 436 performance was partially linked to flow such that fit was improved during periods of low flow, 437 including seasonal or annual periods of low flow. For example, both models at both sites had the 438 best fit during the July-August-September (JAS) period when seasonal flow was minimized. 439

{acro:JAS

{acro:AMJ

Results as annual aggregations suggested that chl-a patterns between years have not been 440 constant and are considerably different between sites (Fig. 3b). Both models showed a gradual 441 and consistent increase in chl-a at LE1.2, with values increasing by approximately 1.5 μ g L⁻¹ 442 from 1986 to 2014. Predictions at TF1.6 did not show a similar increase from the beginning to the 443 end of the time series, although a dramatic decrease from approximately 12 $\mu g \ L^{-1}$ to 6 $\mu g \ L^{-1}$ from 2000 to 2006 was observed. By 2014, chlorophyll returned to values similar to those prior to the initial decrease. Flow-normalized predictions that were averaged annually at each site allowed an interpretation of trends that were independent of variation in discharge or salinity (Tables 3 447 and 4). Overall percent change of chl-a concentration from the beginning to the end of the time 448 series at LE1.2 was approximately 20% (Table 3). A slight decrease in chl-a at TF1.6 was 449 observed from 1986 to 2014 (Table 4). Changes by annual, seasonal, and flow time periods at

LE1.2 were comparable for each time period and model type, although some differences were observed. For example, both models had maximum increases in chl-a for the different flow 452 periods for high levels of flow (20% for GAMs, 22.3% for WRTDS). Trends by different time 453 periods were more apparent for TF1.6, particularly as an overall decrease in chl-a for both models 454 during the 2001–2007 period and an overall increase during 2008–2014 period (Table 4). 455 Seasonal changes were especially pronounced during the JFM and October-November-December (OND) periods where both models showed an increase and 457 decrease, respectively, with differences between the two (JFM period, 5.7% for GAMs, 32.7% for 458 WRTDS; OND period, -13.6% for GAMs, -17.5% for WRTDS). Percent changes by flow 459 period were also observed at TF1.6, with the most noticeable difference from LE1.2 being a 460 decrease in chl-a during both high and low flow (both models) and relatively larger increases in 461 chl-a during moderate flow. 462

3.2 **Comparison of model predictions**

463

471

475

476

477

480

The following describes comparisons of model results, whereas the previous section 464 emphasized results relative to trends over time and fit to the observed data. Accordingly, direct 465 comparisons between model predictions provided a means of identifying instances when models 466 results were systematically different from each other. Table 5 compares average differences and 467 RMSE of results between each model for the complete time series and different subsets by 468 annual, seasonal, and flow periods. Overall, differences between the models were minor with 469 most percent differences not exceeding 1% and only one RMSE value greater than 0.20 (RMSE 470 0.22 for JFM at TF1.6). The greatest differences between the models were observed in the seasonal comparisons, with the most extreme differences observed at LE1.2 for the JAS (5.03%, 472 WRTDS greater than GAMs) and OND (-5.25, WRTDS less than GAMs) periods. Differences 473 between stations were not apparent.

Regressions comparing model results provided additional information about overall differences (significantly different intercept) and differences between the models that varied for different values (significantly different slope) (Table 6, Fig. 5). No significant differences were observed for the entire time series such that estimated intercepts and slopes were similar to zero and one, respectively, for both stations and model predictions (observed and flow-normalized). However, differences were observed for the time period subsets, with the most obvious

differences occurring for the seasonal aggregations. For example, all comparisons between the models for both sites and model predictions had intercept estimates significantly greater than zero and slope estimates significantly less than one for the JAS period (Table 6). All site and model prediction comparisons also had significantly different intercept and slope estimates for the low flow time period. Visual comparisons of results in Fig. 5 confirm those in Table 6, particularly differences in the seasonal aggregations. For example, comparisons of WRTDS and GAMs results for the JFM period at TF1.6 showed an intercept greater than zero and a tendency for GAM estimates to be higher than WRTDS at the right-side of the distribution (i.e., slope less than one with the regression line below 1:1).

3.3 Changes in chlorophyll response to flow over time

Both models described chlorophyll response with sufficient parameterization of input variables to evaluate variation with flow changes over time. As in Beck and Hagy III (2015), changes in the relationship of chl-a to flow can be evaluated by predicting observed chl-a across the range of observed flow (or salinity) values for each year in the time series. Visual information obtained from these plots are useful to identify periods of time when chl-a was or was not related to changes in flow and may also lead to the development of hypotheses regarding changes in drivers of primary production, e.g., temporal shifts in point-sources to non-point sources of pollution (Hirsch et al. 2010, Beck and Hagy III 2015). The only difference between the models in creating such plots is that the three-dimensional prediction grid of chl-a, flow, and time created during model fitting is used for WRTDS, whereas the plots for GAMs are based on post-hoc model predictions with novel data.

Fig. 6 shows the estimated changes from each model in predicted chl-a for salinity (LE1.2) or flow (TF1.6) across all years in the study period. The plots are also separated by months of interest to isolate effects of seasonal variation. Visual assessment of the plots suggests that the relationships were dynamic across the study years and varied considerably between LE1.2 and TF1.6. For example, the October plots show an decreasing sensitivity of chl-a with inreasing flow (decreasing salinity) at LE1.2 from early to late in the time series (i.e., a strong, positive relationship changing to a weak relationship over time). Conversely, the opposite trend is observed at TF1.6 in October such that a weak relationship with flow is observed early in the time series and a strong, negative relationship is observed later in the time series, although overall

chl-*a* has decreased over time. Additionally, both models provided similar indications of the
changes over time, regardless of site or time of year. However, some differences between the
models were observed, particularly for January at LE1.2 where WRTDS provided a wider range,
or potentially less stable response of chl-*a* to salinity changes in the earlier years.

3.4 Flow-normalization with simulated data

WRTDS and GAMs were fit to each dataset creating six models to evaluate the general fit 516 of observed to predicted ($Chl_{obs} \sim \widehat{Chl}_{obs}$) and biological to flow-normalized chl-a 517 $(Chl_{bio} \sim \widehat{Chl}_{bio})$. Models were fit using identical methods as those for the Patuxent time series 518 such that an optimal window width combination for WRTDS and optimal degrees of freedom for smoothing parameters with GAMs were identified. Fig. 8 shows an example of the changing 520 relationships between chl-a and flow across the simulated time series using the results from three 521 optimal WRTDS models. The plots confirm those in Fig. 7 by showing the varying effects of flow 522 in each simulated dataset over time (no effect, constant, increasing) and that the models 523 appropriately characterized the relationships. For example, a changing response of chl-a to 524 salinity is apparent in the third panel of Fig. 8 such that no response is observed early in the time 525 series followed by an increase in the response of chl-a to flow later in the time series. Similar 526 patterns were observed for the GAMs. 527

Comparisons of fit to the simulated time series showed no systematic differenes between 528 the models. Overall, WRTDS results had lower RMSE than GAMs for all comparisons except one $(Chl_{obs} \sim \widehat{Chl}_{obs})$, constant flow simulation), although differences in performance were minor 530 (Table 7). Visual comparison of results suggested that both models provided comparable 531 information for predictions of observed values and flow-normalized predictions (Fig. 9). 532 Additionally, the varying effect of flow on each time series was apparent in comparisons of 533 predicted with flow-normalized results, such that \widehat{Chl}_{bio} was increasingly different from \widehat{Chl}_{obs} from no effect to constant effect of the flow component (top row, Fig. 9). Although both models 535 provided similar performance for individual simulations, differences between the simulations 536 were observed. The different effects of flow had a negative effect on the ability of each model to 537 remove the flow component. Comparisons of Chl_{bio} with \widehat{Chl}_{bio} showed the lowest RMSE with 538 no flow effect and the highest with a constant flow effect (Table 7). Different flow effects did not 539 have an influence on the relationship between predicted (\widehat{Chl}_{obs}) and observed (Chl_{obs}) chl-a such that RMSE for all models and simulations were similar and lower than those comparing the flow-normalized results. Overall, changing the flow component primarily affected the ability of each model to reproduce the flow-normalized component (\widehat{Chl}_{bio}) with relatively minor differences between the models.

568

4.1 Model comparisons and considerations

The objectives of different statistical models can define methods for comparing relative 547 abilities. As applied to estuaries, both WRTDS and GAMs have the objective of describing trends from long-term monitoring datasets, whereas practical applications of each model (e.g., 549 hypothesis testing, assessment of management actions, etc.) will be defined by future needs or 550 research objectives. Accordingly, our comparison methods were chosen based on the exploratory 551 objectives of the analysis and that each technique provides a novel approach to trend assessment. 552 We evaluated predictive performance of both observed and flow-normalized trends, comparison 553 between models for potential bias and indications of trend, and descriptions of canonical variation 554 related to temporal or flow effects. The variety of methods for comparing models can provide 555 different information depending on the desired application. An improvement in predictive 556 performance using RMSE, for example, may suggest one model is more advantageous over 557 another if the goal is to reproduce trends, whereas this information may be irrelevant for hypothesis testing. Inferior performance for one metric does not necessarily invalidate an analysis 559 method for all potential applications. An interpretation of the results should consider that the 560 analysis provides an overview with several techiques, given that the purpose of each model will 561 be better defined by future applications.

A general conclusion from our results is that both models provide similar information, both in predictive performance and trends over time in the Patuxent. The comparisons of RMSE consistently showed that WRTDS had lower prediction error than GAMs for all scenarios. A naive interpretation may suggest that WRTDS is a superior model given these results, but we emphasize that the improvement in performance is trivial both in the relative values and differences in the theoretical foundations of each model. Morever, prediction error for GAMs could easily be improved over WRTDS with only a slight adjustment of model parameters. This

highlights a potential pitfall of using prediction error as a performance metric because the values are sensitive to tuning parameters and the statistical characteristics of a training dataset. To 571 address this issue, comparable methods for model development were implemented to legitimize 572 the comparisons of predictive performance. Both WRTDS and GAMs used a form of 573 cross-validation to identify an optimal parameter space that minimized the bias-variance tradeoff 574 on separate training and test datasets. A more generic interpretion of the benefits of cross-validation is that model development is not biased by analyst intervention as the parameters 576 are chosen with predefined heuristics. Although further development of the technique is needed, 577 this paper presents the first application of a statistical method of selecting optimal window widths 578 for WRTDS. This method allowed for a valid comparison model performance and will likely facilitate future applications of the model to alternative datasets.

The comparisons of predictive performance for each model should also be interpreted 581 relative to the statistical foundations of each model. The smoothing process in GAMs, although 582 mathematically involved, rapidly converges to a solution as compared to the fitting process for 583 WRTDS that requires a unique regression estimate for every point in the time series. From a 584 practical perspective, the comparable error estimates for each model's predictions suggests that 585 GAMs are advantageous because there appears to be little benefit of the added computational 586 time of WRTDS. More surprisingly, the characterization of dynamic changes in flow relationships 587 over time appear comparable for each model. For example, Fig. 6 shows similar information for 588 each model although different methods defined by the models were used to describe chl-a 589 changes over time with variation in salinity or flow. A simple grid of explanatory variables 590 spanning the distribution space of the observed variables was used as input for the fitted GAMs, 591 whereas WRTDS results in the same figure used each model's fitted interpolation grid. As such, 592 novel insight into trends over time would be expected with the added computational time required 593 for the WRTDS interpolation grids. Conventional modelling techniques that have a predefined and limited parameter space have been described as 'statistical straightjackets' that mold the data to the model. WRTDS is meant to provide a contrasting approach where the data mold the results, 596 as compared to GAMs that could be considered overconstrained in this context by following a 597 predefined model structure. The results do not provide a compelling contrast between GAMs and 598 WRTDS despite the statistical differences between the models.

The interpretation that WRTDS does not provide additional insight with the added 600 computational time may be misguided. A lack of clear differences between each model could 601 have been related to characteristics of the datasets. The use of data-driven models to identify 602 emergent patterns in the data necessarily requires that these characteristics are real phenomenens 603 that are not readily observed in the raw data. A logical expectation for trend evaluation is that 604 different methods would lead to similar conclusions for datasets that lack dynamic variation, such as differences between flow relationships and response endpoints over time. Similarity in results 606 for WRTDS and GAMs could simply mean that relationships between time, season, and flow in 607 the Patuxent are adequately described by the statistical theories of each approach. A priori 608 site-selection of TF1.6 and LE1.2 was meant to capture a gradient of watershed to mainstem 609 influences on productivity at each location. The known historical changes from management practices (e.g, wastewater treatment, banning of phosphorus-based detergents) and natural events 611 (e.g., storm events, seagrass recovery) that have affected the Patuxent have also provided a unique 612 context for the time series. The assumption that these characteristics of the datasets will translate 613 to differences in the model results may have been misguided given that we were not able to show clear differences. Generalizations of the relative merits of each model should be made sparingly until additional assessments with alternative datasets are made. Finally, comparability between 616 the two methods may also suggest that both models were equally bad at describing dynamic 617 relationships in the dataset. An assumption throughout the analysis that is not entirely 618 unreasonable is that both models were equally 'good', although the possibility that both were equally inadequate should also be considered as a potential explanation. Alternative drivers of 620 chlorophyll response that are not explicity included in each model could limit explanatory power 621 if time, season, and discharge were not the dominant predictors of production. 622

Although our results generally indicated that comparable information was provided by both models, instances were also observed when different information was provided. Descriptions of canonical variation of seasonal trends from the model predictions suggested that WRTDS more adequately characterized seasonal minima and maxima in chlorophyll production. Although both similarly described the general structure of seasonal peaks at each station, WRTDS provided greater distinction of the secondary seasonal maxima (Fig. 4, September/October peak at LE1.2, May/June peak at TF1.6). A post-hoc assessment of seaonal variation at each station showed that

623

626

627

628

GAMs poorly characterized the secondary seasonal peak during the last ten years of the time series despite the peak being present in the observed data. A quantitative comparison of predictions by seasonal time periods also suggested that differences between the models were 632 more often observed during specific months within each year (Tables 5 and 6 and Fig. 5), as 633 compared to variation between different annual or flow periods. The potential for WRTDS to more adequately characterize seasonal variation in chl-a patterns deserves additional attention, 635 particularly if changes in observed chl-a for specific months of the year have occurred at a 636 monitoring station. Cloern and Jassby (2010) emphasize the importance and potential difficulty of characterizing different components of chl-a variability. WRTDS applied to tidal waters could 638 prove a valuable tool to develop a more comprehensive understanding of spatio-temporal 639 variation in phytoplankton variability.

631

637

Differences between the models may also indicate potential shortcomings, in addition to 641 advantages. The computationally intensive fitting method for WRTDS was expected to allow 642 additional insight into variation of chl-a in response to the primary drivers of time, discharge, and 643 season. This novel information was investigated several ways, including comparisons of model peformance, evaluations of time periods or flow-normalized trends, or a simple visual distinction 645 between model results. As noted above, seasonal differences were observed between the models, 646 whereas the additional comparisons suggested both methods provided comparable information. 647 However, initial assessment of Fig. 6 suggested that WRTDS provided a more dynamic 648 description of chl-a response to changes in flow or salinity over time for specific locations in the record. For example, chl-a response over time to salinity changes during January at LE1.2 shows 650 WRTDS describing greater variation than GAMs, particularly for lower salinity values. 651 Additional investigation suggested that these 'novel' descriptions were related to low sample size 652 for the specific location in the record causing instability in the model predictions. Accordingly, 653 WRTDS descriptions may be unstable at extreme or uncommon locations in the data domain where the number of observations with non-zero weights may be limited. Methods for WRTDS have been developed to address this issue (i.e., automated window width increases with low 656 sample sizes), although they were not implemented for the current analysis due to complications 657 during model fitting and interpretations of trend comparisons with GAMs.

4.2 Patuxent trends

677

678

679

680

681

682

683

684

685

688

Both models provided a detailed description of water quality changes in the Patuxent 660 River estuary. Although our primary objective was to evaluate the quantitative capabilities of each 661 model, several trends were described that deserve additional investigation. Each model described 662 distinct trends at TF1.6 and LE1.2 that were linked to changes over time and discharge, having 663 implications for assessing the effects of additional factors related to ecosystem condition. Annual 664 trends at TF1.6 showed a substantial decrease in chl-a that lasted several years, followed by a 665 gradual increase to earlier concentrations. By comparison, annual trends in the lower estuary at 666 LE1.2 showed a consistent increase over time. Seasonal patterns and trends related to different flow periods were also described by the models. Spring blooms were commonly observed in the 668 lower estuary, whereas late summer blooms were observed in the upper estuary. Trends related to 669 different flow periods were less obvious, although large increases in chl-a were observed for 670 moderate flow levels. Trends in Fig. 6 can facilitate an interpretation of changes at each station 671 related to flow effects over time. For example, annual trends in October suggested that the association between flow (decreasing salinity) and chl-a over time have weakened at LE1.2. By contrast, trends at TF1.6 showed an increasingly negative relationship between flow and chl-a 674 over time. Both models also showed changes in the shape of the relationship between chl-a and 675 discharge (e.g., January at LE1.2). 676

Although an investigation of the specific causes of these changes is beyond the scope of our analysis, the model results can be used to hypothesize links between factors that influence water quality in the context of temporal and flow variation. Changes in flow relationships over time have been linked to shifts in sources of nutrient pollution (Hirsch et al. 2010, Beck and Hagy III 2015). Specific results for the Patuxent could be related to historical changes in nutrient loading, such as the banning of phosphorus-based detergents in the mid 1980s and wastewater treatment plant upgrades in the early 1990s (Lung and Bai 2003, Testa et al. 2008). An investigation of chlorophyll response over time to both flow changes and ratios of point-source to non-point sources of nutrients could provide valuable information on system dynamics. Historical changes in flow have also had noticeable impacts on water quality in the Patuxent. A drought period from 1999 to 2002 contributed to increases in chl-*a* in the upper estuary and decreases in the lower estuary. By contrast, storm events have been linked to lower chl-*a* from estuarine

flushing or shifts in concentration along the longitudinal axis. The model results partially confirm the observed changes in chl-a with flow changes, particularly in the tidal fresh portion of the 690 upper estuary. The substantial decline in chl-a in the early 2000s coincides with storm events, 691 including the passage of Hurricane Isabel in 2003. However, low concentrations persisted for 692 several years suggesting that additional factors could had separate or additive effects on chl-a 693 response. Seagrass growth patterns in the upper estuary have followed a similar but inverse 694 pattern as chl-a with an increase in growth in the late 1990s and early 2000s, followed by a 695 decline in recent years after a peak in coverage in 2005 (J. Testa, personal communication). This 696 correlation with chl-a suggests nutrient sequestration by seagrasses following a shift in primary 697 production, although definitive links have yet to be shown. Results from both models could be 698 used to develop a more ecologically robust evaluation of water quality changes in the Patuxent having potential implications for the larger Chesapeake Bay area. 700

Table 1: Summary characteristics of monitoring stations on the Patuxent River estuary. Chlorophyll and salinity values are based on averages from 1986 to 2014. Stations used for the analysis are in bold. Segments are salinity regions in the Patuxent for the larger Chesapeake Bay area (TF = tidal fresh, OH = oligohaline, MH = mesohaline). See Fig. 1 for site locations.

Station	Lat	Long	Segment	Distance (km)	Depth (m)	\ln -Chl (μ g L $^{-1}$)	Sal (ppt)
TF1.3	38.81	-76.71	TF	74.90	2.9	1.52	0.00
TF1.4	38.77	-76.71	TF	69.50	2.0	2.31	0.02
TF1.5	38.71	-76.70	TF	60.30	10.6	2.88	0.27
TF1.6	38.66	-76.68	OH	52.20	6.2	2.44	0.90

Table 2: Summaries of model performance using RMSE of observed to predicted ln-chlorophyll for each station (LE1.2 and TF1.6). Deviance for each model as the sum of squared residuals is shown in parentheses. Overall performance for the entire time series is shown at the top with groupings by different time periods below. Time periods are annual groupings every seven years (top), seasonal groupings by monthly quarters (middle), and flow periods based on quantile distributions of discharge.

Table 3: Summaries of flow-normalized trends from each model at LE1.2 for different time periods. Summaries are averages and percentage changes of ln-chlorophyll ($\mu g \ L^{-1}$) based on annual means within each category. For example, summary values for high flow for a given model and are based on instances of high flow across years. Percentage changes are the differences between the last and first years in the periods. Time periods are annual groupings every seven years (top), seasonal groupings by monthly quarters (middle), and flow periods based on quantile distributions of discharge.

WRTDS	0.53 (32.8)	0.57 (38.9)	
Increasing flow			
GAM	0.51 (31.2)	0.54 (35.0)	
WRTDS	0.50 (29.7)	0.52 (31.9)	

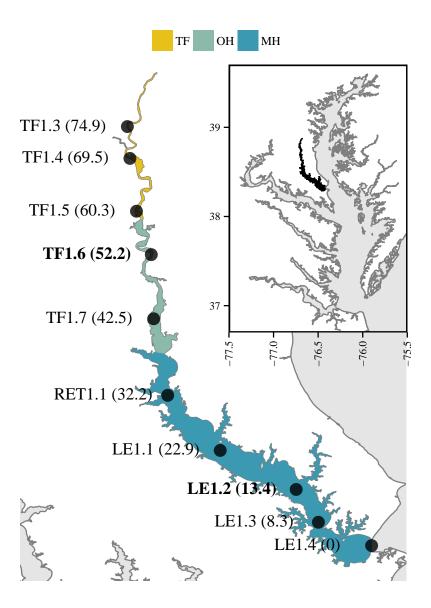

Fig. 1: Patuxent River estuary with Chesapeake Bay inset. Fixed locations monitored by the Chesapeake Bay Program at monthly frequencies are shown along the longitudinal axis with distance from the mouth (km). Study sites are in bold. Salinity regions in the Patuxent for the larger Chesapeake Bay area are also shown (TF = tidal fresh, OH = oligohaline, MH = mesohaline). See Table 1 for a numeric summary of station characteristics.

{fig:map}

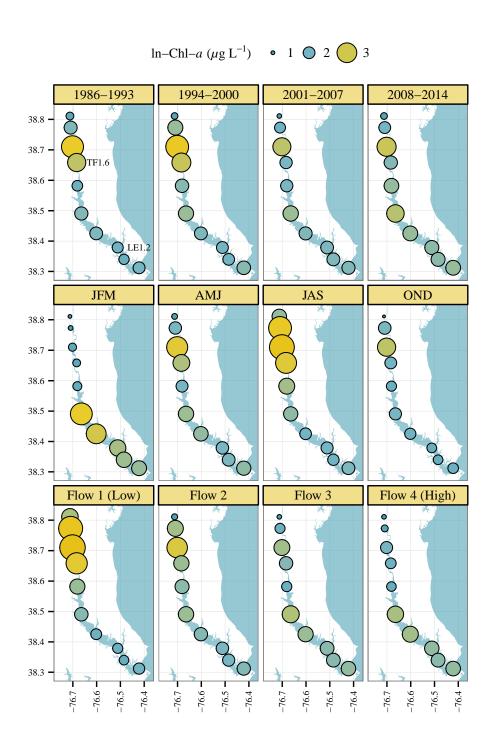

Fig. 2: Annual, seasonal, and flow differences in chlorophyll trends at each monitoring station in the Patuxent River Estuary. Size and color are proportional medians of ln-chlorophyll-a by year, season, and flow categories. See Fig. 1 for station numbers.

{fig:chly:

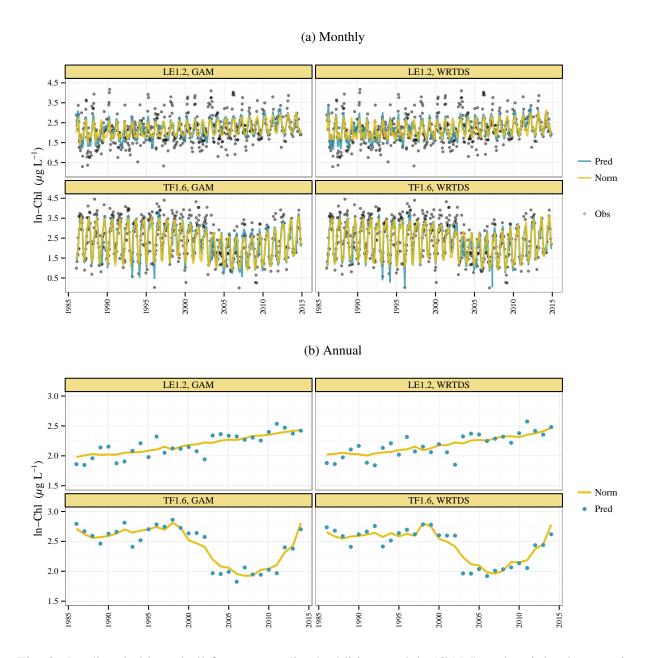

Fig. 3: Predicted chlorophyll from generalized additive models (GAM) and weighted regression (WRTDS) for LE1.2 and TF1.6 stations on the Patuxent River estuary. Fig. 3a shows results at monthly time steps and Fig. 3b shows results averaged by year. Values in blue are model predictions and values in yellow are flow-normalized predictions.

{fig:pred

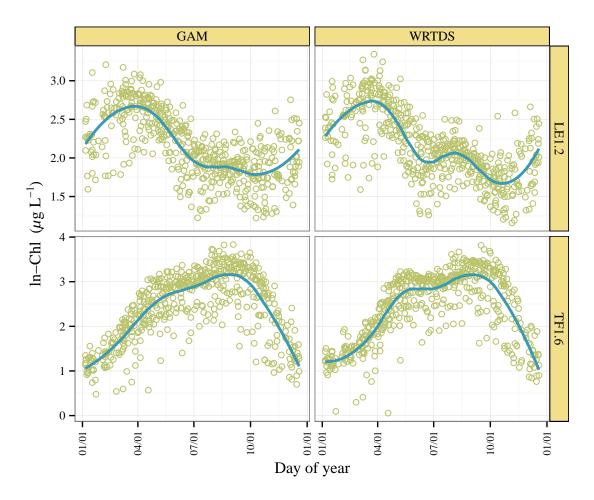

Fig. 4: Seasonal variation of predictions by station and model. Points are all model predictions by day of year from 1986 to 2014. The blue line is a loess (locally estimated) polynomial smooth to characterize the seasonal components.

{fig:seas

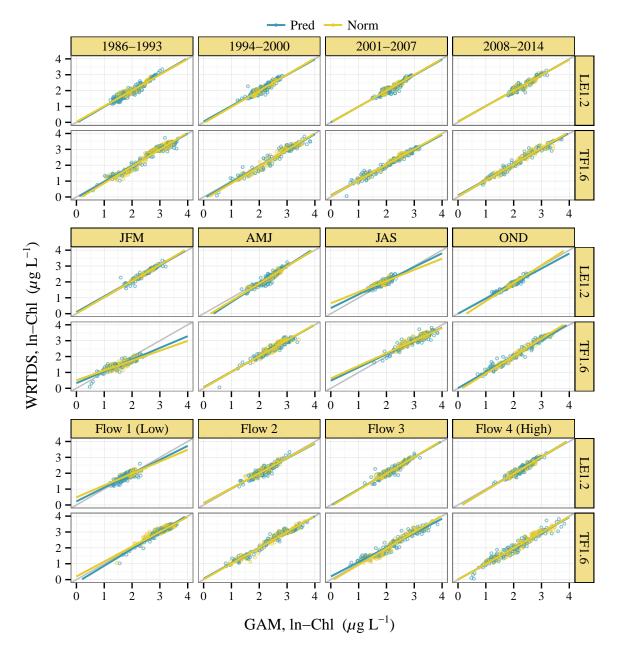

Fig. 5: Comparison of WRTDS and GAMs results at each station (LE1.2, TF1.6) and different time periods. Predicted and flow-normalized results are shown. Time periods are annual groupings every seven years (top), seasonal groupings by monthly quarters (middle), and flow periods based on quantile distributions from the discharge record (low). Regression lines for each model result and 1:1 replacement lines (thin grey) are also shown. See Table 6 for parameter estimates of regression comparisons.

{fig:regp:

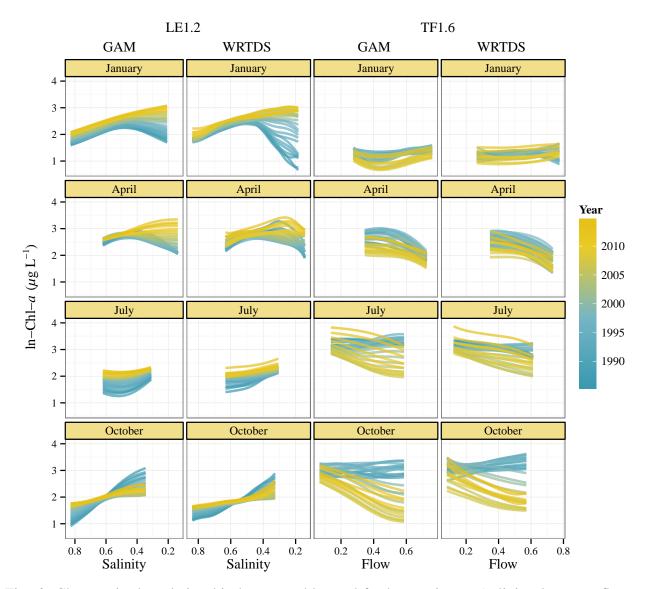

Fig. 6: Changes in the relationship between chl-a and freshwater inputs (salinity decrease, flow increase) across the time series. Separate panels are shown for each station (LE1.2, TF1.6), model type (GAM, WRTDS), and chosen months. Changes over time are shown as different predictions for each year in the time series (1986 to 2014). Salinity was used as a tracer of freshwater inputs at LE1.2, whereas the flow record at Bowie, Maryland was used at TF1.6. The scales of salinity and flow are reversed for comparison of trends. Units are proportions of the total range in the observed data with values in each plot truncated by the monthly 5th and 95th percentiles.

{fig:dyna:

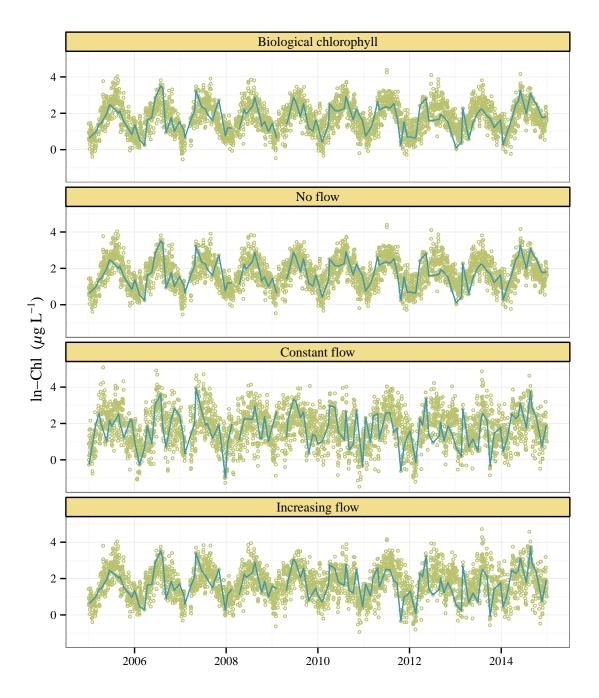

Fig. 7: Examples of simulated time series for evaluating flow-normalized results from WRTDS and GAMs. The plots show the simulated daily time series (points) and monthly samples (lines) from the daily time series used to evaluate the flow-normalized predictions from WRTDS and GAMs. From top to bottom, the time series show the biological chl-a independent of flow and the three simulated datasets that represent different effects of flow: none, constant, and increasing effect. The flow-normalized results for the simulated monthly time series from each model were compared to the first time series (biological chlorophyll) that was independent of flow.

{fig:sime:

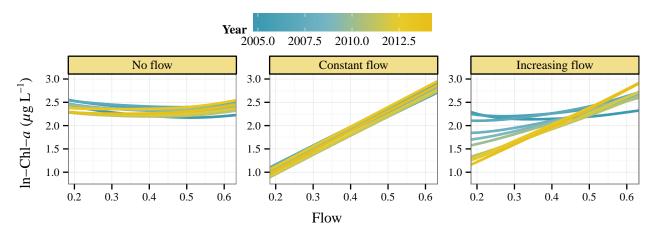

Fig. 8: Examples of changing relationships between chl-a (μ g L $^{-1}$) and flow (as proportion of the total range) over time (2005–2015) for each simulated time series in Fig. 7. The plots are based on August predictions from three WRTDS models for each time series to illustrate the simulated relationships between flow and chlorophyll.

{fig:dyna

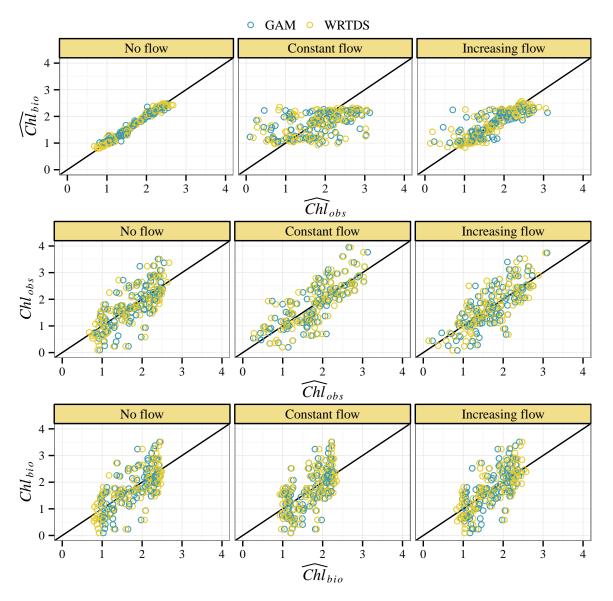

Fig. 9: Model predictions for three simulated datasets with different flow contributions (none, constant, increasing). Estimated variables (e.g., \widehat{Chl}_{bio}) are compared to simulated variables (e.g., Chl_{bio}) to evaluate the ability of each model (GAMs and WRTDS) to recreate the flow-normalized time series of chlorophyll (i.e., bottom plot, \widehat{Chl}_{bio} vs Chl_{bio}) after removing a simulated flow component from the observed chlorophyll time series (Chl_{obs}).

{fig:simre
